

Abstract of the Disclosure:

An intradyne receiver provides a received intradyne signal \underline{X} which comprises at least two, mutually phase-shifted, and N-ary phase shift keyed intradyne part signals X_k . Here $N=2$ for binary and $N=4$ for quaternary PSK. For carrier recovery purposes their frequency is multiplied by a factor of N in an intradyne frequency multiplier FM. After passing a lowpass filter TPY the filtered, frequency-multiplied intradyne signal is passed through an intradyne frequency divider IDF1, IDF2 with carrier intradyne signals $\underline{C1}$, $\underline{C2}$ as output signals that allow to demodulate the received intradyne signal \underline{X} . The intradyne frequency divider undertakes more than one state change while changing the phase of the carrier intradyne signal by $2\pi/N$. It can be formed as a regenerative intradyne frequency divider. When used for coherent optical data transmission this allows to tolerate comparatively large laser line widths.
